

CHEMICAL BONDING

- Electrophiles are elements having positive charge due to loss of electrons.
- Nucleophiles are atoms having negative charge due to gain of electrons.
- Electronegativity is the ability of an atom to attract to itself an electron pair shared with another atom in a chemical bond.
- The greater its value, greater the power of an atom to attract the electrons in a covalent bond towards itself.
- Its value increases up each group.
- Its value increases from Grp I to Grp VII.
- Fluorine is the most electronegative element.
- Value decreases down a group.
- Halogens have highest values of electronegativity.
- Non-metals have higher value while metals have lesser value of electronegativity.

→ Factors influencing it.

- Nuclear charge: atoms in same period with greater +ve nuclear charge are more likely to attract bonding pair of electrons.
- Atomic radius: Inversely proportional. As atomic radius increases, nuclear force of attraction to other electrons is less, so electronegativity is less.

- Shielding : Higher shielding effect means lower nuclear force of attraction and thus less electronegativity.
- Oxidation number : If ON is +ve, the element lacks electrons so electronegativity will be more. If its +2 it's even more than when its +1.
- The most commonly used scale of electronegativity values is called the Pauling electronegativity scale, N.

Since electronegativity of carbon > hydrogen, the electrons will shift towards C if they were to combine.

Thus AlF_3 is more ionic than AlCl_3 even though they are both covalent bonds.

$$\text{AlCl}_3 - E(\text{Cl}) - E(\text{Al}) = 3 - 1.5 = 1.5$$

$$\text{AlF}_3 - E(\text{F}) - E(\text{Al}) = 4 - 1.5 = 2.5 \approx$$

Ionic Bonding (Electrovalent bond)

- +ve ions are formed when atoms lose e^- (cations)
- -ve ions are formed when atoms gain e^- (Anions)
- Individual ions are never stable. An opposite charge ion with same charge must be present to stabilize the ion.
- The force of attraction between +ve and -ve ions is called electrostatic force of attraction.

When ions are formed the atoms resemble configuration of their nearest noble gas.

Isoelectronic elements are

The ions in a compound having same electronic structure are termed as isolectronic ions.

Eg: MgO . These form very stable bonds (lattices) and thus their MP and BP is very high.

Properties of ionic compounds

- They form when atoms connect to one another by ionic bonds.
- Ionic bonds are the strongest chemical bonds.
- One atom have partial +ve charge while other has partial -ve charge.
- Ionic compounds have high MP and BP.
- They form crystal lattices rather than amorphous solids.
- They have high enthalpies of fusion and vaporization.
- They are hard and brittle.
- They conduct electricity when in water.

Covalent Bonding

- (i) Element with high IE → difficult to lose e^-
- (ii) Element with low EA (electron affinity)
 - ↳ difficult to gain e^-

Since, it difficult to lose and gain electrons, the electrons are shared between the elements and thus covalent bond is formed.

Electron affinity is the amount of energy released^{/changed/ involved} when electrons are added to one mole of the gaseous ions to form negative ions / ions with lesser charge.

Electrons that gain e^- easily have high EA.

F^- at radius < F^- at radius

Bonds like $C \equiv C$ have nucleus very close which repel each other making $C \equiv C$ unstable, thus $C \equiv C$ can't exist.

Effective covalent bonds will only form when they are at a certain threshold distance and such that the two atoms have lost their energy and are at lower energy states.

In electron affinity once an electron is added to $O \rightarrow O^{*-}$ to form O^{*-} , the extra e^- will reduce its radius and thus there'll be less there'll be repulsion to another electron and thus more energy is to be supplied.

Addition of first $\pm e^-$ is exothermic while second e^- is endothermic.

Properties of covalent compounds

- They have relatively low MP. and BP.
- Most covalent compounds are gaseous.
- Have low enthalpy of fusion.
- Tend to be soft & flexible.
- They also tend to be more flammable.
- They don't separate in water and thus aren't electrical conductors.
- They also don't dissolve in water very well.

CHEMICAL BONDING...

(coordinate covalent bond)

When there is sharing of e^- but only one of the elements contributes the e^- .

Ion pair \bar{e} deficient
 e^- rich as all $3e^-$ are
 This has used and only
 $2e^-$ $6e^-$ are left
 \downarrow still needs $2e^-$
 Lewis base Lewis acid

Coordinate covalent
 bond / dative bond
 \rightarrow indicates contrib
 ution.
 Ammonium boron
 trifluoride (Salt)

Only pairs of electrons can be contributed.
 Single e^- donation isn't possible.

(iv) H_3PO_4 # CH_3OH 

N₂O₃

NH₄NO₃

(CHEMICAL BONDING...)

O₃

Al₂Cl₆

Properties of coordinate covalent bond compounds.

- It is semi polar and non ionizable bond.
- It is directional in nature so coordinate compounds have definite molecular geometry and many show geometrical isomerism.
- Their properties fall between true ionic and true covalent compounds.

Valence shell electron pair repulsion theory

- The shapes of molecules
- In 1874, Dutch chemist Jacobus van't Hoff suggested for the first time that molecules possess a definite, unique, 3d shape whose shape is determined by angles between bonds and the bond angles are determined by arrangement of electrons.
- Angles between pairs will depend on number of pairs around the atom.
- Electrons try to be farthest due to repulsion.

$$\theta = \theta$$

CHEMICAL BONDING...

THE LEWIS MODEL

XeF_2

ClF_3

Lone pair - lone pair \rightarrow lone pair - bond pair \rightarrow bond pair - bond pair

PF_3

Here chlorine is kept as such because $\text{P}-\text{F}$ bond angle is always 120° , but if Cl were on top $\text{P}-\text{F}$ bond angle is 90° , which is less. This is case for different atoms.

Metallic bonding

Study of metallic properties bonding helps explain metallic properties like conduction of heat and electricity, malleability + ductility.

In a pure metallic element, all atoms are identical. If we look closely at most metallic lattices we find that atoms are arranged similar to argon atoms in solid argon.

A basic metal molecule. Here electrostatic force is neutralized and thus the electrons remain stationary.

This attraction between electron cloud and metal ions is metallic bonding.

They are very strong as they resemble ionic bonding.

- When stress is applied the atoms slide, thus creating malleability.
- When electricity (electrons) are supplied to metal one electron displaces other and thus conduction is possible.
- Delocalized electrons don't belong to any particular atom.
- These delocalised electrons displace each other when potential difference is supplied.

Some attractions

Ar

Substance	formula	Attraction	MP
Argon	Ar	Weak dipole	
Hydrogen chloride	HCl	Dipole-Dipole	
Water	H ₂ O	H ₂ bonding	Increases
Iodine	I ₂	Strong dipole	
Sucrose	C ₁₂ H ₂₂ O ₁₁	Strong " bonding "	

- + Metals have high MP and BP due to great attraction however some covalent compounds with a giant lattice (macromolecules) like diamond tend to have even higher MP & BP.
- + In metals, valence electrons don't belong to any particular nuclei so they are free and mobile.
- + When photons strike metals, e⁻ get excited and jump to higher energy levels which is followed by almost immediate reemission of visible light causing lusture

Na-metal

- + Mercury is liquid because it is big atom but loses less electrons thus attraction between Hg⁺ & e⁻ is less making Hg⁺ farther apart.

→ They also have high tensile strength due to strong attraction.

Alloys

- Metallic substance made by mixing and fusing two or more metals or a metal & non metal to observe qualities like strength & hardness.
- They generally have superior properties than its parent metal.
- Resist corrosion.
- Example Brass and Bronze made of Copper and Zinc in different ratios.

The overlap of orbitals

σ -bond

- S-S orbitals overlap
- S-P orbitals overlap
- P-P orbitals overlap

internuclear distance (bond length)

internuclear axis

BONDING EXERCISE

1. Solid NaCl and MgO are held by ionic bonds. Write symbols and electronic configuration for each of the ions.

- a) i) Na^+ (2,8) ii) Cl^- (2,8,8)
- iii) Mg^{2+} (2,8) iv) O^{2-} (2,8)

b) Explain what holds Na^+ and Cl^- ions together in the solid crystal.

→ Na^+ and Cl^- ions are of opposite charges. So, they attract each other. This coulombic force of attraction is what holds the ions together.

c) NaCl melts at 1074 K; MgO melts at 3225 K. Both have identical structures. So, why is there such a difference?

→ The magnitude of charges attracting each other is twice that of NaCl in MgO. So, the ionic bond in MgO is stronger than that of NaCl, and thus it requires more heat energy to break its bonds.

2. Write down the electronic structures of the following ions and also in terms of s, p & d orbitals.

a) S^{2-}

2,8,8

$1\text{s}^2 2\text{s}^2 2\text{p}^6 3\text{s}^2 3\text{p}^6$

b) F^-

2,8

$1\text{s}^2 2\text{s}^2 2\text{p}^6$

2, 8, 8, 6 2, 8, 14

2, 8, 11

2, 8, 16

2, 8, 18, 18, 8

2, 8, 18, 18, 2

2, 8, 18, 18

2, 8, 18, 18, 8

2, 8, 18, 18

3. Write formulae for following ionic compounds.

a) sodium sulphide $\rightarrow \text{Na}_2\text{S}$ b) caesium bromide $\rightarrow \text{CsBr}$ c) Magnesium nitride $\rightarrow \text{Mg}_3\text{N}_2$ d) chromium (III) oxide $\rightarrow \text{Cr}_2\text{O}_3$ e) tin (II) chloride $\rightarrow \text{SnCl}_2$ f) nickel (II) selenide $\rightarrow \text{NiSe}$ g) aluminium oxide $\rightarrow \text{Al}_2\text{O}_3$ h) copper (I) iodide $\rightarrow \text{CuI}$

4. A covalent bond consists of a pair of shared electrons between two atoms. How does this shared pair hold the two atoms together?
- + The pair of shared electrons is required for both atoms to attain stable electronic configuration. However, except for in diatomic molecules, one atom attracts the electrons with more force, causing them to shift slightly. However, the other atom also doesn't want to let go of the electrons due to it being in stability. This creates an a stable state, where both the atoms are sharing the electrons, thus holding them together.

5. Draw dots and crosses diagrams for:

(i) NH_3

(ii) H_2S

(iii) HI

(iv) NCl_3

(v) BF_3 

F

F - B - F

6. Explain how the covalent bonding in the given compounds arises.

a) PCl_5

→ There are 5 electrons in the outermost shell of Phosphorus. However it can hold 5 more electrons and extend to $4s^2$ orbital to be stable with configuration $4s^2$. Thus, it shares one electron each with chlorine, leaving chlorine in stable octet state, and itself with 20 electrons and being stable. Thus five covalent bonds are formed.

b) SF_6

→ There are 6 electrons in the outermost shell of Sulfur. But it can hold 6 more electrons due to extended d subshell, to attain stable configuration. Thus, it shares one electron each with Fluorine making Fluorine stable and gaining 6 electrons itself to be stable. Thus six covalent bonds are formed.

→ Xenon initially has 8 electrons in its outermost shell. However, it also can use other unused subshells in 4th shell, and thus hold more than 8 electrons. So, it will form four covalent bonds to combine with four fluorine atoms, thus having a total of 12 electrons itself.

A. Xenon forms several compounds, but neon doesn't. Suggest why it is so?

→ It is so because neon has a configuration of $1s^2 2s^2 2p^6$ which means in both of its shells, all the subshells are used up. So it doesn't cannot utilize any other subshell to accommodate electrons to form bonds. However xenon can utilize unused subshells in 4th shell to accommodate electrons.

8. Please fill the table shown.

→ AX_4 - bond pair

→ AX_3E - (bond pair, lone pair)

→ AX_2E_2 - trigonal planar, (bond pair, lone pairs)

→ AX_3 - bond pair

→ AX_2E - trigonal planar, (bond pair, lone pair)

METALLIC BONDING EXERCISE

1. K (a) and Sc follow each other in periodic table.
Their MP and BP is given.

	Potassium	Calcium	Scandium
MP	336 K	1112 K	1814 K
BP	1033 K	2757 K	3204 K

- a) Write their electronic configuration.

- b) Each of them are held together by metallic bonding.

Explain the nature of it using K as example.

→ Metallic bonding can be explained using a model.

In this model, the atoms of metals lose electrons to form an electron soup. The positively charged ions attract the electrons from this soup.

In potassium, the K^+ ions attract an electron due to their charges. However, the same e^- is attracted by other K^+ ions with equal magnitude leaving the electron still and the atoms to bond with this attractive force.

- c) The metallic bonding isn't completely broken until a metal boils. State what happens to the bond strength as you go from K to Sc.

→ Since the amount of energy required to break the bond (BP) increases, the strength of bond also increases from K to Sc.

d) Explain the effect from part c.

→ The energy required to break the attraction between the electrons and ions in a metallic lattice increases from K to Sc. This is because as more energy is supplied, the atoms vibrate more rapidly thus making them separate.

1a) Mg has higher MP and BP than Na. This can be explained in terms of electronic structures, packing and atomic radii. Explain why they cause the MP and BP of Mg to be higher.

In Mg, the 3s orbital is completely filled. Thus, this causes the electrons to be attracted by more force which in turn decreases the atomic radius of Mg than of Na. So, the electrostatic force of attraction between atom and e^- in Mg is more than that of Na. Also, in the lattice two Mg atoms share $2e^-$, while in Na, two atoms only share $1e^-$. Thus the bond force for Na is weaker than that of Mg. This in turn causes MP & BP of Mg to be higher.

2. Explain why metals are good conductors of electricity and heat.

→ In a metallic lattice, there are some delocalized free electrons which don't belong to any particular atom. When a potential difference is supplied to a metal, the free e^- can accelerate and help transfer electricity from one point

to another fast, making them good conductors of electricity. Similarly when heat is provided, the same free electrons move due to kinetic energy and can transfer this heat between atoms easily making them good conductors of heat as well.

3a) Pure metals are malleable and ductile. Explain the two words.

→ Malleable means very easy to turn into thin sheets by and ductile means very easy to draw into wires.

b) If a metal is subjected to small stress - it will return to its original shape when stress is removed however large stress causes permanent deformation. Explain this using diagrams.

Fig 1.

Fig 2.

In Fig 1, the low stress isn't enough to break the metallic bonding between atoms so it doesn't undergo permanent deformation, however in Fig 2, the high stress is enough to break the bonding between two atoms and bond the atoms with new atoms. Thus even when stress is removed, deformation remains as the atoms have bonded with new atoms.

c) When a blacksmith works with metals, they are heated, hammered and re-heated. Explain what's happening in terms of electro structure of metal.

→ The metals need to be reshaped into desirable shape. When they are heated, their bonding in lattice becomes weaker, so it is easier to deform them with ~~an~~ lesser stress. But the metals lose heat to their surrounding fast so they need to be reheated to work with as the lattice bonding becomes stronger again and it needs to ~~be~~ be made weaker.

d) why is brass harder than copper and zinc, its constituent metals.

→ Brass is harder than its constituent metals as the lattice of brass consists of atoms of both copper and zinc, which are of different sizes. This unevenness in lattice makes it more difficult to slide the lattice layers, thus increasing hardness.

CHEMICAL BONDING

Hybridization

- It is the mixing of orbitals.
- Orbitals must be in same shell to undergo hybridization

All four covalent bonds are similar as there is same bond length, bond energy, same distance from each other.

$\text{C}-1s^2 2s^2 2p^2$ 2nd shell electrons can hybridize, but not first.
 $\text{H}-1s^2$

So, there is overlapping of p-orbital of C and s-orbital of H.

Ground state configuration
can't form 4 covalent bonds
as there are only 2-unpaired electrons.

Excited state configuration
when one e^- from 2s orbital goes to 2p. But still the bonds won't be similar as 2s orbitals have less energy than 2p.

- So, to make the bonds similar the 2s and 2p orbitals combine to form sp^3 hybridization

This orbital is called sp^3 orbital

Orientation of orbitals will be. (in methane)

Tetrahedral shape and $109^\circ 28'$ angle.
Degenerate orbitals (with same energy)

Triangular planar shape with 120° angle between them.

5-sigma bonds.

While rotating this double bond, the weak π -bond will break, disintegrating the molecule. Thus, double bond has restricted rotation.

Electronegativity and bonding

Electronegativity of an atom is the measure of ability of an atom to attract a shared pair of e⁻s towards itself. It increases across a period and decreases down the group.

H	2.1
Li	1.0
Be	1.5
B	2.0
C	2.5
N	3.0
O	3.5
F	4.0
Na	
Mg	
Al	
Si	
P	
S	
Cl	

Linus Pauling studied the pauling electronegativity & introduced pauling electronegativity scale.

Polar bond

Covalent bond in which the bonding electrons are distributed unequally due to difference in electronegativity of the bonded atoms.

$$\text{Electronegativity difference} = 3.5 - 2.1 = 1.4$$

$$\text{C-O} \rightarrow 1.0$$

$$\text{O-H} \rightarrow 1.4$$

$$\text{Al-Cl} \rightarrow 2.0$$

Dipole: Drift of bonded electrons to the more electronegative atom resulting in separation of charge. ($+ \rightarrow -$) (μ)

$(\text{Cl}_4 -$ Tetrachloromethane (Carbon tetrachloride)

Dipole moment: Measure of the polarity of the molecule.

CH_3Cl - Chloromethane

CH_3OH , C_2H_6 , CH_2Cl_2 , SF_4

INTERMOLECULAR FORCES

Force between molecular entities other than those due to bond formation. Also called van der Waal's force.

- Instantaneous dipole - Induced dipole (Id-Id)
Also known as London dispersion force.

Even for non polar compounds like Br_2 , dipole is induced for a short while due to random motion of electrons. This short moment dipole is called Instantaneous dipole.

When A Bromine A has induced dipole, it induces a dipole in its neighbour Bromine B, which now has its induced dipole. The bond / force of attraction between A and B is London dispersion force.

This phenomenon is not very common in Cl_2 as it has lower amount of electrons than bromine, thus the force is rather small, which is why chlorine exists as a gas, bromine as liquid and iodine as solid.

Size of force depends on no. of electrons present in the molecules and no. of contact points between molecules (alkanes)

Uses

- To find trend in boiling and melting points.
- To find enthalpy of vaporization. (ΔE_{vp})

The graph is the same for boiling and melting points. However none hit absolute zero.

- Permanent dipole - permanent dipole

They have strong molecular force of attraction so their boiling point is high due to permanent nature of polarity.

This bond is the strongest. This is 10x stronger than other permanent dipole bonds due to high electronegativity of Fluorine. 10x weaker than covalent bond.

This special bond is called Hydrogen bond.

Conditions of Hydrogen bond are:

- One molecule of H must bond with electronegative atoms like F, O and N.
- Second molecule should have F, O or N with lone pair of electrons (available pair of electrons).

No. of Hydrogen bonds per molecule depends on :-

- 1 No. of lone pairs in second atom.
- 2 No. of H atoms attached to electronegative atom.

13a) Ethanol, C_2H_5OH and water.

b) ammonia and water

Why is water's density more than that of ice?

- In ice each water molecule makes hydrogen bonds with other molecules forming tetrahedral shape.

Tetrahedral shape in ice.

→ This structure of ice causes it to have larger intermolecular separation, decreasing ~~the~~ increasing volume but having less mass. But in water the intermolecular separation is less so it can occupy lesser volume.

Propanone and water

Methanol and trichloromethane

ethanal and water
